**Abstract.** First order logic provides a convenient formalism for describing a wide variety of verification conditions. Two main approaches to checking such conditions are pure first order automated theorem proving (ATP) and automated theorem proving based on satisfiability modulo theories (SMT). Traditional ATP systems are designed to handle quantifiers easily, but often have difficulty reasoning with respect to theories. SMT systems, on the other hand, have built-in support for many useful theories, but have a much more difficult time with quantifiers. One clue on how to get the best of both worlds can be found in the legacy system Simplify which combines built-in theory reasoning with quantifier instantiation heuristics. Inspired by Simplify and motivated by a desire to provide a competitive alternative to ATP systems, this paper describes a methodology for reasoning about quantifiers in SMT systems. We present the methodology in the context of the Abstract DPLL Modulo Theories framework. Besides adapting many of Simplify's techniques, we also introduce a number of new heuristics. Most important is the notion of *instantiation level* which provides an effective mechanism for prioritizing and managing the large search space inherent in quantifier instantiation techniques. These techniques have been implemented in the SMT system CVC3. Experimental results show that our methodology enables CVC3 to solve a significant number of benchmarks that were not solvable with any previous approach.

## 1 Introduction

Many verification problems can be solved by checking formulas in first order logic. Automated theorem proving (ATP) systems are much more powerful than those of just a few years ago. However, practical verification conditions often require reasoning with respect to well-established first order theories such as arithmetic. Despite their power, ATP systems have been less successful in this domain. A new breed of provers, dubbed SMT solvers (for Satisfiability Modulo Theories) is attempting to fill this gap.

* This work was partially supported by a donation from Intel Corp. and by the National Science Foundation grant number 0551645.

Solvers for SMT are typically based on decision procedures for the satisfiability of quantifier-free formulas in certain logical theories of interest. As a result, they have been traditionally rather limited in their ability to reason about quantifiers, especially when compared to ATP systems. A notable exception is the prover Simplify [7] which combines a Nelson-Oppen style prover with heuristics for instantiation of quantifiers. Simplify has been successfully applied in a variety of software verification projects including ESC/JAVA [9], and, despite its age, it is still considered state-of-the-art for SMT reasoning with quantifiers.

However, Simplify has a number of drawbacks. Chief among them is the fact that it is old and no longer supported. Additionally, there are several weaknesses in Simplify's heuristics, so that often users must spend considerable manual effort rewriting or annotating their input formulas before Simplify can successfully prove them. Finally, modern SMT solvers have a host of performance and feature enhancements that make them more appealing for use in applications. Unfortunately, users of SMT solvers have had to choose between these improvements and effective quantifier support.

In this paper we discuss efforts to update and improve quantifier reasoning in SMT solvers based on the DPLL($T$) architecture [10]. We begin by extending the Abstract DPLL Modulo Theories framework [11], a convenient abstract framework for describing such systems, with rules for quantifiers. We then explain the main heuristics employed by Simplify as strategies within this framework, and introduce several improvements to Simplify's strategies. Most novel is the notion of *instantiation level* which is an effective means of prioritizing and managing the many terms that are candidates for quantifier instantiation.

The techniques discussed in the paper have been implemented in CVC3, a modern DPLL($T$)-style solver based on a variant of the Nelson-Oppen combination method [3, 4]. We conclude with experimental results demonstrating the effectiveness of our heuristics in improving the performance of CVC3 and in solving verification conditions (in particular, several from the NASA suite introduced in [6]) that no previous ATP or SMT system has been able to solve.

## 2 Background

We will assume the usual notions and adopt the usual terminology in first order logic with equality. We also assume familiarity with the fundamentals of unification theory (see, e.g., [1]). For brevity, when it is clear from context, we will refer to an atomic formula also as a term. If $\varphi$ is a first-order formula or a term, $t$ is a term, and $x$ is a variable, we denote by $\varphi[x/t]$ the result of substituting $t$ for all free occurrences of $x$ in $\varphi$. That notation is extended in the obvious way to tuples $\overline{x}$ of variables and $\overline{t}$ of terms. The notation $\exists\overline{x}.\varphi$ stands as usual for a formula of the form $\exists x_1.\exists x_2.\cdots\exists x_n.\varphi$ (similarly for $\forall\overline{x}.\varphi$).

The *Satisfiability Modulo Theories* problem consists of determining the satisfiability of some closed first order formula $\varphi$, a *query*, with respect to some fixed *background theory* $T$ with signature $\Sigma$. Often it is also desirable to allow the formula to contain additional *free symbols*, i.e. constant, function, and predicate

symbols not in $\Sigma$. We say that $\varphi$ is $T$-satisfiable if there is an expansion of a model of $T$ to the free symbols in $\varphi$ that satisfies $\varphi$. Typical background theories in SMT are (combined) theories $T$ such that the $T$-satisfiability of ground formulas (i.e. closed quantifier-free formulas possibly with free symbols) can be decided by a special-purpose and efficient procedure we call a *ground SMT solver*.

Most modern ground SMT solvers integrate a propositional SAT solver based on the DPLL procedure with a *theory solver* which can check satisfiability of sets of literals with respect to some fragment of $T$. The Abstract DPLL Modulo Theories framework [2, 11] provides a formalism for this integration that is abstract enough to be simple, yet precise enough to model many salient features of these solvers. The framework describes SMT solvers as transition systems, i.e., sets of *states* with a binary relation $\Longrightarrow$ over them, called the *transition relation*, defined declaratively by means of *transition rules*. A state is either the distinguished state *Fail* (denoting $T$-unsatisfiability) or a pair of the form $M \parallel F$, where $M$ is a sequence of literals currently assumed to hold and $F$ is a formula in conjunctive normal form (CNF) which is being checked for satisfiability.

Assuming an initial state of the form $\emptyset \parallel F_0$, the goal of the transition rules is to make progress towards a *final* state while maintaining equisatisfiability of the formula $F_0$. A final state is either *Fail* or a state $M \parallel F$ such that (i) the set of literals in $M$ is $T$-satisfiable, and (ii) every clause in $F$ is satisfied by the assignment induced by $M$ (i.e., assuming that the literals in $M$ are all true). In the latter case, the original formula $F_0$ is $T$-satisfiable. We refer the reader to [2, 11] for a complete description of the framework. As a sample of its rules we describe here the propositional and the theory propagation rule:

$$\textsf{UnitPropagate}: \quad M \parallel F, C \vee l \implies M\ l \parallel F, C \vee l \ \textbf{if} \begin{cases} M \models \neg C \\ l \text{ is undefined in } M \end{cases}$$

$$T\text{-}\textsf{Propagate}: \quad M \parallel F \implies M\ l \parallel F \quad \textbf{if} \begin{cases} M \models_T l \\ l \text{ or } \neg l \text{ occurs in } F \\ l \text{ is undefined in } M \end{cases}$$

In the above rules, a comma is used to separate clauses of the CNF formula, $C$ and $l$ respectively denote a clause and a literal, $\models$ is propositional entailment, and $\models_T$ is first-order entailment modulo the background theory $T$.

## 3 Reasoning with Quantifiers in SMT

While many successful ground SMT solvers have been built for a variety of theories and combinations of theories, extending SMT techniques to quantified queries has proven so far quite difficult. This mirrors the difficulties encountered in first order theorem proving, where quantified queries are the norm, in embedding background theories *efficiently* into existing refutation-based calculi.

Following Stickel's original idea of *theory resolution* [15], several first order calculi have been given sound and complete theory extensions that rely on the computation of complete sets of theory unifiers. These nice theoretical results have, however, failed to generate efficient implementations thus far, mostly due

to the practical difficulty, or the theoretical impossibility, of computing theory unifiers for concrete background theories of interest.

Recently, attempts have been made to embed ground SMT procedures into successful first-order provers, most notably Vampire [14] and SPASS [18], while aiming at practical usefulness as opposed to theoretical completeness (see, e.g., [12]). The work described here follows the alternative, also incomplete, approach of extending SMT solvers with effective heuristics for quantifier instantiation.

### 3.1 Modeling Quantifier Instantiation

The Abstract DPLL Modulo Theories framework can be easily extended to include rules for quantifier instantiation. The key idea is to also allow closed quantified formulas wherever atomic formulas are allowed. We define an *abstract atomic formula* as either an atomic formula or a closed quantified formula. An *abstract literal* is either an abstract atomic formula or its negation; an abstract clause is a disjunction of abstract literals. Then, we simply replace ground literals and clauses with their abstract counterparts. For instance, non-fail states become pairs $M \parallel F$ where $M$ is a sequence of abstract literals and $F$ is a conjunction of abstract clauses.

With this slight modification, we can add the two rules below to Abstract DPLL to model quantifier instantiation. For simplicity and without loss of generality, we assume here that abstract literals in $M$ appear only positively (if they are negated, the negation can be pushed inside the quantifier) and that the bodies of abstract atoms are themselves in abstract CNF.

$$\exists\text{-Inst}: \quad M \parallel F \implies M \parallel F, \neg\exists\overline{x}.\varphi \vee \varphi[\overline{x}/\overline{c}] \quad \textbf{if} \begin{cases} \exists\overline{x}.\varphi \text{ is in } M \\ \overline{c} \text{ are fresh constants} \end{cases}$$

$$\forall\text{-Inst}: \quad M \parallel F \implies M \parallel F, \neg\forall\overline{x}.\varphi \vee \varphi[\overline{x}/\overline{s}] \quad \textbf{if} \begin{cases} \forall\overline{x}.\varphi \text{ is in } M \\ \overline{s} \text{ are ground terms} \end{cases}$$

The $\exists$-Inst rule identifies a quantified abstract literal $\exists\overline{x}.\varphi$ currently in $M$. This formula is then *instantiated* with fresh constants $\overline{c}$ to get $\varphi[\overline{x}/\overline{c}]$. A clause is then added that is equivalent to the implication $\exists\overline{x}.\varphi \rightarrow \varphi[\overline{x}/\overline{c}]$. Note that we cannot just add $\varphi[\overline{x}/\overline{c}]$ because the Abstract DPLL Modulo Theories framework requires that the satisfiability of $F$ be preserved by every rule. The $\forall$-Inst rule works analogously except that the formula is instantiated with ground terms rather than fresh constants.

*Example 1.* Suppose $a$ and $b$ are free constant symbols and $f$ is a unary free function symbol. We show how to prove the validity of the formula $(0 \leq b \wedge (\forall\, x.\, x \geq 0 \rightarrow f(x) = a)) \rightarrow f(b) = a$ in the union $T$ of rational arithmetic, say, and the empty theory over $\{a, b, f\}$. We first negate the formula and put it into abstract CNF. Three abstract unit clauses are the result: $0 \leq b \ \wedge \ \forall\, x.\, (x \not\geq 0 \vee f(x) = a) \ \wedge \ f(b) \neq a$. Let $l_1, l_2, l_3$ denote the three abstract literals in the

above clauses. Then the following is a derivation in the extended framework:

$$
\begin{array}{lrcll}
 & \emptyset & \| & l_1,\, l_2,\, l_3 & \text{(initial state)} \\
\Longrightarrow^* & l_1\, l_2\, l_3 & \| & l_1,\, l_2,\, l_3 & \text{(by UnitPropagate)} \\
\Longrightarrow & l_1\, l_2\, l_3 & \| & l_1,\, l_2,\, l_3,\, \neg l_2 \vee b \not\geq 0 \vee f(b) = a & \text{(by } \forall\text{-Inst)} \\
\Longrightarrow & l_1\, l_2\, l_3\, b \geq 0 & \| & l_1,\, l_2,\, l_3,\, \neg l_2 \vee b \not\geq 0 \vee f(b) = a & \text{(by } T\text{-Propagate)} \\
\Longrightarrow & \mathit{Fail} & & & \text{(by Fail)}
\end{array}
$$

The last transition is possible because $M$ falsifies the last clause in $F$ and contains no decisions (case-splits). As a result, we may conclude that the original clause set is $T$-unsatisfiable, which implies that the original formula is valid in $T$.

It is not hard to see, using an analysis similar to that in [2], that the $\exists$-Inst and $\forall$-Inst rules preserve the satisfiability of $F$ and therefore the soundness of the transition system. It is also clear that termination can only be guaranteed by limiting the number of times the rules are applied. Of course, for a given existentially quantified formula, there is no benefit to applying $\exists$-Inst more than once. On the other hand, a universally quantified formula may need to be instantiated with several different ground terms to discover that a query is unsatisfiable. For some background theories (e.g., universal theories), completeness can be shown for exhaustive and fair instantiation strategies that consider all possible quantifier instantiations by ground terms. This result, however, is of little practical relevance because of the great inefficiency of such a process. In this paper we focus on strategies for applying $\forall$-Inst that forgo completeness in the interest of efficiency, and simply aim at good *accuracy*, understood ideally here as the ratio of proved over unproved unsatisfiable queries in a given set.

## 4 Strategies for Instantiation

### 4.1 Instantiation via Matching

A naive strategy for applying rule $\forall$-Inst is the following: once $\forall$-Inst has been selected for application to an abstract literal $\forall\, \overline{x}.\varphi$, the rule is repeatedly applied until $\overline{x}$ has been instantiated with every possible tuple of elements from some finite set $G$ of ground terms. A reasonable choice for $G$ is the set of ground terms that occur in assumed formulas (i.e., in $M$). We call this approach *naive instantiation*. A refinement of this strategy for sorted logics is to instantiate $\overline{x}$ with all and only the ground tuples of $G$ that have the same sort as $\overline{x}$. Somewhat surprisingly, naive instantiation is sufficient for solving a large number of quantified verification conditions (see Section 6). Still, there are many verification conditions for which naive instantiation is hopelessly inefficient because of the large number of candidates for instantiation.

The Simplify prover uses a better heuristic, that still applies $\forall$-Inst exhaustively to an abstract atom, but selects for instantiation only ground terms that are *relevant* to the quantified formula in question, according to some heuristic relevance criteria. The idea is as follows: given a state $M \parallel F$ and an abstract literal $\forall\, x.\varphi$ in $M$,[1] try to find a subterm $t$ of $\forall x.\varphi$ properly containing $x$, a

[1] The general case of an abstract literal of the form $\forall \overline{x}.\varphi$ is analogous.

ground term $g$ in $M$, and a subterm $s$ of $g$, such that $t[x/s]$ is equivalent to $g$ modulo the background theory $T$ (written $t[x/s] =_T g$). In this case, we expect that instantiating $x$ with $s$ is more likely to be helpful than instantiating with other candidate terms. Following Simplify's terminology, we call the term $t$ a *trigger* (for $\forall x.\varphi$). In terms of unification theory, the case in which $t[x/s] =_T g$ is a special case of *$T$-matching* between $t$ and $g$.

In general, in the context of SMT, given the complexity of the background theory $T$, it may be very difficult if not impossible to determine whether a trigger and a ground term $T$-match. The simplest solution is to check only for syntactic matching, by attempting to unify each trigger with each ground term. Simplify implements a simple extension of syntactic matching based on the congruence closure of the ground equations in $M$ (see [7] for details).

*Example 2.* Consider again the formula in Example 1. At the point where ∀-Inst is applied, $M$ consists of the following sequence of literals: $0 \leq b, \forall x.\ (x \not\geq 0 \vee f(x) = a), f(b) \neq a$. There are four ground terms appearing in $M$: 0, $a$, $b$, and $f(b)$. Thus, naive instantiation would apply ∀-Inst four times, once for each ground term. On the other hand, Simplify's matching heuristic would first identify a trigger in $\forall x.\ (x \not\geq 0 \vee f(x) = a)$. Since a trigger must be a term properly containing the quantified variable, the only candidate is $f(x)$. Now the trigger is compared with the set of ground terms. There is a single match, with $f(b)$, obtained when $x$ is bound to $b$. Thus, the matching heuristic selects the ground term $b$ for instantiation.

### 4.2 Eager Instantiation versus Lazy Instantiation

So far, we have been concerned with the question of *how* to apply the rule ∀-Inst to a given abstract atom. An orthogonal question is *when* to apply it. One strategy, which we call *lazy instantiation*, is to apply ∀-Inst only when it is the only applicable rule. At the opposite end of the spectrum, another strategy, which we call *eager instantiation*, is to apply ∀-Inst to a universally quantified formula as soon as possible (i.e., as soon as it is added to the current $M$).

In Simplify, propositional search and quantifier instantiation are interleaved. When Simplify has a choice between instantiation and case splitting, it will generally favor instantiation. Thus, Simplify can be seen as employing a form of eager instantiation. Others [8] have advocated the lazy approach. One advantage of lazy instantiation is that an off-the-shelf SAT solver can be used. Eager instantiation typically requires a more sophisticated SAT solver that can accept new variables and clauses on the fly. We compare eager and lazy instantiation in Section 6 below.

## 5 Improving Instantiation Strategies

In this section we describe several improvements to the basic strategies discussed above. These strategies are implemented in CVC3 and evaluated in Section 6.

### 5.1 Triggers

Consider a generic quantified formula $\forall \overline{x}.\varphi$. The first step in the matching strategy described above is to find triggers within $\varphi$. CVC3 improves on Simplify's automated trigger generation methods in several ways. In CVC3, every subterm or non-equational atom $t$ of $\varphi$ that contains all the variables in $\overline{x}$ and at least one function or predicate symbol is considered a viable trigger. For example, if $\overline{x} = \{x_1, x_2\}$, then $x_1 \leq x_2$ and $g(f(x_1 + y), x_2)$ are legal triggers, but $0 \leq x_1$ and $f(x_1) + 1 = x_2$ are not. Simplify is slightly more restrictive: it requires that a trigger contain no additional variables besides those in $\overline{x}$. For example, in the formula $\forall x.(f(x) \rightarrow \forall y.g(x, y) < 0)$, the term $g(x, y)$ is not a viable trigger for Simplify because it contains $y$ which is not bound by the outermost quantifier. Our experiments show that this restriction is unnecessary and does cause a loss of accuracy in some cases (in particular, CVC3's better performance on the *nasa* benchmarks described in Section 6.3 is partly due to relaxing this restriction).

*Avoiding instantiation loops.* Simplify uses a simple syntactic check to prevent its instantiation mechanism from diverging; specifically, it discards a potential trigger $t$ if certain (syntactical) instances of $t$ occur elsewhere in the formula. For example, in $\forall x.P(f(x), f(g(x)))$, the term $f(x)$ will not be selected as a trigger because an instance of $f(x)$, namely $f(g(x))$ occurs in the formula. While simple and inexpensive, this static filtering criterion is unable to detect more subtle forms of loops. For example, consider a state $M \parallel F$ with $M$ containing the abstract literal $\psi = \forall x.\, (x > 0 \rightarrow \exists y.\, f(x) = f(y) + 1)$ where $f$ is free. The only trigger for $\psi$ is $f(x)$ and Simplify has no reason to reject this trigger. Now, if the set of ground terms contains $f(3)$, say, then with an application of $\forall$-Inst, it is possible to add the abstract clause $\neg\psi \vee \exists y.\, f(3) = f(y) + 1$ to $F$. Then, with an application of UnitPropagate and of $\exists$-Inst the literal $f(3) = f(c_1) + 1$, with $c_1$ fresh, can be added to $M$. The introduction of $f(c_1)$ in the set of ground terms can now give rise to a similar round of rule applications generating a new term $f(c_2)$, and so on. In order to prevent such loops, in addition to Simplify's static loop detection method, CVC3 also implements a general method for dynamically recognizing loops (including loops caused by groups of formulas together) and disabling the offending triggers. We do not describe that method here, partly due to space constraints but mainly because the *instantiation level* heuristic described in Section 5.4 below is much more effective.

*Multi-trigger generation.* Sometimes, there are no triggers that contain all the variables in $\overline{x}$. In this case, Simplify generates *multi-triggers*: small sets of terms in $\varphi$ which together contain all (and exactly) the free variables in $\overline{x}$. CVC3 has essentially the same mechanism but it limits the number of multi-triggers composed of atomic formulas of $\varphi$. It does this by putting together in a multi-trigger only atoms having the same polarity in the overall abstract CNF formula $F$—where polarity is defined as usual for negation normal form formulas like $F$.

### 5.2 Matching algorithm

Like all DPLL($T$) systems, CVC3 checks the satisfiability of a query modulo some background theory $T$ by maintaining at all times a current set $M$ of assumed abstract literals. Ideally, when looking for matches for triggers, one would want to apply theory matching modulo the union of $T$ and $M$. As mentioned earlier, however, because of the richness of $T$ alone, in general this is highly impractical, if possible at all. CVC3 instead uses a (rather) incomplete theory matching procedure which is easier to implement efficiently, and, as we show in the next section, provides good results experimentally.

As $M$ is modified, CVC3 also computes and stores in its data structures the congruence closure $E$ of the positive ground literals of $M$ over the set $G$ of all ground terms in $M$. For any theory $T$, any two terms equal modulo $E$ are also equal modulo $T \cup M$. Then, to apply the rule $\forall$-Inst to an abstract literal $\forall \overline{x}.\varphi$, CVC3 generates ground instantiations for $\overline{x}$ by matching modulo $E$ the triggers of $\forall \overline{x}.\varphi$ against the terms in $G$. CVC3 implements a sound and terminating $E$-matching procedure by extending the standard rule-based syntactic unification algorithm as explained below.

Given a trigger $t$ of the form $f(t_1, \ldots, t_n)$ where $f$ is a free symbol, we select from $G$ all terms of the form $f(s_1, \ldots, s_n)$; for each of these terms we then try to solve the (simultaneous) unification problem $\{t_1 =^? s_1, \ldots, t_n =^? s_n\}$. Standard unification fails when it encounters the case $g(\overline{t}) =^? g'(\overline{s})$ (where $g$ and $g'$ are distinct symbols). In contrast, we do not immediately fail in this case.

In general, when we select an equation of the form $g(\overline{t}) =^? s$, we do not fail in the following two subcases: (i) $g(\overline{t})$ is ground and $g(\overline{t}) =_E s$,[2] and (ii) $g$ is a free symbol and there is a term of the form $g(\overline{u})$ in $G$ such that $s =_E g(\overline{u})$. In the first case, we just remove the equation $g(\overline{t}) =^? s$; in the second case, we replace it by the set of equations $\overline{t} =^? \overline{u}$.

For a simple example, consider matching a trigger like $f(h(x))$ with a ground term $f(a)$ where $f, h, a$ are free symbols and $x$ is a variable. Suppose that $a = h(s) \in E$ for some $s$. Then the procedure above can generate the non-syntactic unifier $\{x \mapsto s\}$.

It is not difficult to see using standard soundness and termination arguments that this unification procedure converges, and when it does not fail it produces a grounding $E$-unifier (in fact, an $E$-matcher) for the problem $f(t_1, \ldots, t_n) =^? f(s_1, \ldots, s_n)$. This unifier is applied to the body of the abstract atom $\forall x.\varphi$ to obtain the clause for $\forall$-Inst. The procedure is clearly incomplete because $E$-matching is usually non-unitary[3], but the procedure returns only one solution, chosen arbitrarily, just for simplicity and speed. This source of incompleteness, however, has not shown to be a major limitation in practice so far.

The instantiation mechanism above applies to triggers whose top symbol is a free function symbol. Triggers whose top symbol is a theory symbol are currently

[2] Due to the way the congruence closure $E$ is maintained in CVC3, checking that $g(\overline{t}) =_E s$ takes nearly always constant time.

[3] In other words, $E$-matching problems can have multiple, incomparable solutions. Consider the previous example with also $a = h(s') \in E$ for some $s' \neq_E s$.

treated the same way unless the symbol is an arithmetic symbol. Triggers starting with $+$ or $*$ are just discarded because treating those symbols syntactically is ineffectual and treating them semantically, as AC symbols say, is too onerous. A trigger $t$ of the form $t_1 < t_2$ or $t_1 \leq t_2$, is processed as follows.[4] For every ground atom $p$ of the form $s_1 < s_2$ or $s_1 \leq s_2$ in $M$, CVC3 generates the $E$-matching problem $\{t_1 =^? s_2, t_2 =^? s_1\}$ if $t$ has positive polarity and $p$ occurs in $M$, or $t$ has negative polarity and $\neg p$ occurs in $M$; otherwise it generates the problem $\{t_1 =^? s_1, t_2 =^? s_2\}$.

### 5.3 Special Instantiation Heuristics

In addition to $E$-matching, CVC3 also employs some specialized instantiation heuristics that have proven useful on the kinds of formulas that appear in practical verification conditions. For simplicity, we will refer to these heuristics too as "trigger matching" even if they are not based on matching in the technical sense of unification theory. Some of these heuristics depend on recognizing that a certain free predicate symbol is defined in the query as an antisymmetric or a transitive symbol. Special multi-triggers are set up for these symbols that take those properties into account to improve the usefulness of the instances generated.

Another heuristic applies to formulas involving CVC3's built-in theory of arrays, which defines a read and a write operator. All triggers of the form $\mathit{read}(\mathit{write}(a, x, v), i)$ where $x$ is one of the quantified variables, in addition to acting as normal triggers, also cause $x$ to be instantiated to the index term $j$ of any ground term of the form $\mathit{read}(a, j)$ or $\mathit{write}(a, j, u)$. The rationale is that when instantiating a variable that is used as an index to an array, we want to consider all known ground array index terms. Usually there are not too many of these terms and the standard matching techniques do not discover all of them.

### 5.4 Trigger Matching by Instantiation Levels

In SMT problems coming from verification applications, one of the main targets of CVC3, the query is a formula of the form $\Gamma \wedge \neg\varphi$ where $\varphi$ is a verification condition and $\Gamma$ is a large and more or less fixed $T$-satisfiable collection of (quantified) axioms about a number of relations and functions that are relevant to the verification application but for which there is no built-in solver. A large number of these axioms typically have no bearing on whether the negation of a particular verification condition is $T$-satisfiable with $\Gamma$. With heuristic instantiation, this entails that too many resources might be easily spent in producing and processing instances of axioms unrelated to the formula $\varphi$.

Simplify uses a *matching depth* heuristic to try to address this problem. Each time a new clause is generated by quantifier instantiation, it is assigned a numerical value which is one greater than the largest value assigned so far. This

[4] In CVC3, atoms using $>$ and $\geq$ are normalized internally to $<$ and $\leq$ atoms, respectively.

value is the matching depth of the clause. Later, when a literal must be chosen for a case-split, literals from clauses with a lower matching depth are preferred to those with a higher matching depth.

CVC3 uses a different approach, better suited to systems with a DPLL($T$) architecture—where case splitting is not necessarily clause-based. Instead of giving a score to clauses, CVC3 assigns an *instantiation level* to every ground term it creates. Intuitively, an instantiation level $n$ for a term $t$ indicates that $t$ is the result of $n$ rounds of instantiations. More precisely, all terms in the original query are given an instantiation level of 0. If a formula $\forall\overline{x}.\varphi$ is instantiated with the ground terms $\overline{s}$, and $n$ is the maximum instantiation level of the terms in $\overline{s}$, then all the new terms in $\varphi[\overline{x}/\overline{t}]$ (as well as any new terms derived from them via theory reasoning) are given the instantiation level $n+1$.

CVC3 provides as an option a trigger matching strategy that visits ground terms by instantiation levels. With this strategy, CVC3 matches triggers only against ground terms whose instantiation level is within a current upper bound $b$. This bound, whose initial value can be set by the user, is increased, by one, only when CVC3 reaches a (non-fail) state $M \parallel F$ where $\forall$-Inst is the only applicable rule and all terms with instantiation level less than or equal to $b$ have already been considered.

Trigger matching by instantiation levels has proved very effective in our experiments, discussed in the next session. Here we point out that its inherent fairness has also the derived benefit of neutralizing the possible harmful effects of instantiation loops in the eager instantiation strategy. The reason is simply that each of the new ground terms generated within an instantiation level belongs by construction to the next level, and so will not be considered for matching until all other terms in the current level have been considered. As a consequence, checking for instantiation loops, either statically or dynamically, is completely unnecessary. Moreover, using instantiation levels allows us to enable by default those triggers that static or dynamic loop detection would have disabled. Significantly, we discovered that such triggers are actually necessary to prove many examples.

## 6 Experimental Results

All tests were run on AMD Opteron-based (64 bit) systems, running Linux, with a timeout of 5 minutes (unless otherwise stated) and a memory limit of 1 GB. For our comparisons, we used the latest versions of each prover available to us at the time: CVC3 version 1.1; Vampire 8.1; SPASS 2.2, yices 1.0, and the version of Fx7 available online at `http://nemerle.org/~malekith/smt/en.html` as of February 2007. A more detailed version of all the results discussed here can be found at `http://www.cs.nyu.edu/~barrett/cade07`.

### 6.1 Benchmarks

The benchmarks for our evaluation are from the SMT-LIB library [13] of benchmarks for SMT solvers. It consists of 29004 benchmarks from three different SMT

divisions: AUFLIA (arrays, uninterpreted functions, and linear integer arithmetic); AUFLIRA (arrays, uninterpreted functions, and mixed linear integer and real arithmetic); and AUFNIRA (arrays, uninterpreted functions, and mixed non-linear integer and real arithmetic). They are further subdivided according to families. In AUFLIA, there are five families: *Burns*, *misc* (we lumped the single benchmark in the *check* family in with *misc*), *piVC*, *RicartAgrawala*, and *simplify*. In AUFLIRA, there are two families: *misc* and *nasa*. And in AUFNIRA, there is a single family: *nasa*. We will comment more specifically on two of these families, *nasa* and *simplify*, below. For more information on the other benchmarks and on the SMT-LIB library, we refer the reader to the SMT-LIB website: `http://www.smtlib.org`.

The *nasa* families make up the vast majority of the benchmarks with a total of 28065 benchmarks in two families. These cases are *safety obligations* automatically generated from annotated programs at NASA. Following their introduction in [6], these benchmarks were made publicly available in TPTP format [17], a format for pure first-order logic. We then undertook the task of translating them into the SMT-LIB format and contributing them to the SMT-LIB library. In order to adapt these benchmarks for SMT, several steps were required. First, we removed quantified assumptions that were determined to be valid with respect to the background theories ,[5] in this case arrays and arithmetic, and made sure to use the built-in symbols defined in the SMT-LIB standard. Second, since SMT-LIB uses a many-sorted logic, we had to infer sorts for every symbol. We used the following rules to infer types: (i) The index of an array is of type of integer; (ii) The return type of functions *cos*, *sin*, *log*, *sqrt* is real; (iii) The terms on both sides of infix predicates $=$, $<=$, $>=$, $<$ and $>$, must have the same type; (iv) If the type of a term cannot be deduced by the above rules, it is assumed to be real. According to [6], of the 28065 cases, only 14 are supposed to be satisfiable (the rest are unsatisfiable). However, after running our experiments and carefully examining the benchmarks in their present form in the TPTP library, our best guess is that somewhere around 150 of the cases are actually satisfiable (both in the SMT-LIB format and in the original TPTP format). It is difficult to know for sure since for these cases, no tool we are aware of can reliably distinguish between a truly satisfiable formula and one that is simply too difficult to prove unsatisfiable, and determining this by hand is extremely tedious and error-prone. We suspect that some assumptions present in the benchmarks from [6] were lost somehow before their submission to the TPTP library, but we do not know how this happened. In any case, most of the benchmarks are definitely unsatisfiable and while many are easy, a few of them are very challenging.

The other major family is the *simplify* family, which was translated (by others) from a set of over 2200 benchmarks introduced in [7] and distributed

[5] These are assumptions that were added by hand to enable better performance by ATP systems. They were removed by using CVC3 to automatically check for validity. Note that this returns the benchmarks to a state more faithfully representing the original application.

with the Simplify theorem prover. Only a selection of the original benchmarks were translated. According to the translator, he excluded benchmarks that were too easy or involved non-linear arithmetic [5]. There are 833 benchmarks in this family, all of which are unsatisfiable.

### 6.2 Evaluating the Heuristics

**Table 1.** Lazy vs. eager instantiation strategy in CVC3.

We began by running CVC3 using only naive instantiation (trying both the lazy and eager strategies) on all SMT-LIB benchmarks. Of 29004 benchmarks, 23389 can be solved in negligible time by both the eager and the lazy naive strategies. As a result, these benchmarks are not helpful for evaluating our more sophisticated heuristics and so we have chosen to exclude them from the tables below. Also, there are 16 benchmarks that are known to be satisfiable, including all of the benchmarks in the AUFLIRA/misc family, so we have excluded them as well (we did not exclude any of the nasa benchmarks since we do not know for sure which of them are actually satisfiable).

For the remaining 5599 benchmarks that could not be solved using the naive strategy, we tried the following instantiation strategies: (i) basic trigger/matching algorithm (BTBM) with none of the heuristics described in Section 5; (ii) basic triggers with the smarter matching (BTSM) described in Section 5.2; (iii) same as (ii) except with smart triggers (STSM) as described in Section 5.1;

and finally (iv) same as (iii) but with the instantiation level (IL) heuristic activated. The results are shown in Table 1. Each table lists the number of cases by family. Then, for each of the four strategies, and for each family, we list the number of cases successfully proved unsatisfiable and the *average* time spent on these successful cases.

As can be seen, the basic matching strategy is quite effective on about 4/5 of the benchmarks, but there are still nearly 1000 that cannot be solved without more sophisticated techniques. Another observation is that the eager strategy generally outperforms the lazy strategy, both on average time taken and on number of cases proved. The notable exception is the *simplify* family. On this family, the lazy strategy performs much better for all except the very last column. This can be explained by the fact that the simplify benchmarks are especially susceptible to getting lost due to looping. However, the lazy strategy is not subject to looping, so it does much better (this also explains why the last column is no better than the third column for the lazy strategy–in fact it's a bit worse, which we suspect is simply due to random differences in the order of instantiations). For the other benchmarks, however, eager instantiation is usually helpful and sometimes critical for finding the proof (this is especially true of the *nasa* families). Thus, the instantiation level heuristic can be seen as a way of combining the advantages of both the eager and lazy strategies. There is one nasa case which is particularly difficult and falls just inside the time limit for the first three columns and just outside the time limit in the last column. This is why one fewer nasa case is proved in the last column.

### 6.3 Comparison with ATP systems

One of our primary goals in this paper was to evaluate whether SMT solvers might be able to do better than ATP systems on real verification applications that require both quantifier and theory reasoning. The *nasa* benchmarks provide a means of testing this hypothesis as they are available in both TPTP and SMT-LIB formats (this was, in fact, one of the primary motivations for translating the benchmarks). We also translated the benchmarks into Simplify's format so as to be able to compare Simplify as well. Table 2 compares CVC3 with Vampire, SPASS, and Simplify on these *nasa* benchmarks. For these tests, the timeout was 1 minute. We chose Vampire and SPASS because Vampire and SPASS are among the best ATP systems: Vampire is a regular winner of the CASC competitions [16], and SPASS was the best prover of those tried in [6]. For easier comparison to [6], the benchmarks are divided as in that paper into seven categories: $T_\emptyset$, $T_{\forall,\rightarrow}$, $T_{prop}$, $T_{eval}$, $T_{array}$, $T_{policy}$, $T_{array*}$. The first category $T_\emptyset$ contains the most difficult verification conditions. The other categories were obtained by applying various simplifications to $T_\emptyset$. For a detailed description of the categories and how they were generated, we refer the reader to [6]. We also exclude in this breakdown (as was also done in [6]) the 14 known satisfiable cases, so there are 28051 benchmarks in total.

The first observation is that all solvers can prove most of the benchmarks, as most of them are easy. The ATP systems do quite well compared to Simplify:

| | | Vampire | | SPASS | | Simplify | | CVC3 | |
|---|---|---|---|---|---|---|---|---|---|
| Category | #cases | #unsat | time | #unsat | time | #unsat | time | #unsat | time |
| $T_{\emptyset}$ | 365 | 266 | 9.2768 | 302 | 1.7645 | 207 | 0.0679 | **343** | 0.0174 |
| $T_{\forall,\rightarrow}$ | 6198 | 6080 | 2.1535 | 6063 | 0.6732 | 5957 | 0.0172 | **6174** | 0.0042 |
| $T_{prop}$ | 1468 | 1349 | 4.3218 | 1343 | 1.0656 | 1370 | 0.0339 | **1444** | 0.0058 |
| $T_{eval}$ | 1076 | 959 | 5.6028 | 948 | 0.7601 | 979 | 0.0423 | **1052** | 0.0077 |
| $T_{array}$ | 2026 | 2005 | 1.4438 | 2000 | 0.2702 | 1943 | 0.0105 | **2005** | 0.0048 |
| $T_{array*}$ | 14931 | 14903 | 0.6946 | 14892 | 0.2323 | 14699 | 0.0101 | **14905** | 0.0035 |
| $T_{policy}$ | 1987 | 1979 | 1.4943 | 1974 | 0.2716 | 1917 | 0.0101 | **1979** | 0.0050 |
| Total | 28051 | 27541 | 1.5601 | 27522 | 0.4107 | 27072 | 0.0145 | **27902** | 0.0043 |

**Table 2.** ATP vs SMT

while Simplify is generally much faster, both Vampire and SPASS prove more cases than Simplify. Since at the time these benchmarks were produced, Simplify was the only SMT solver that could support quantifiers, this can be seen as a validation of the choice of ATP systems over SMT solvers at the time.

However, CVC3 dominates the other systems in both time and number of cases solved. There are only 149 cases that CVC3 cannot solve (as mentioned above we suspect most of these are actually satisfiable) and the average time is less than a hundredth of a second. For the most challenging cases, those in $T_{\emptyset}$, CVC3 was able to solve 343 out of 365 cases, significantly more than the provers evaluated in [6] (the best system solved 280). As far as we know, this is the best result ever achieved on these benchmarks. This supports our hypothesis that with the additional quantifier techniques introduced in this paper, modern SMT solvers may be a better fit for verification tasks that mix theory reasoning and quantifier reasoning.[6]

### 6.4 Comparison with other SMT systems

As we prepared this paper, we knew of only two other SMT systems that include support for both quantifiers and the SMT-LIB format: yices and Fx7. Yices was the winner of SMT-COMP 2006, dominating every category. Fx7 is a new system recently developed by Michal Moskal. Unfortunately, the quantifier reasoning techniques used in these systems are not published, but our understanding is that they also use extensions of the matching algorithms found in Simplify.

Table 3 compares Fx7, yices, and CVC3 on the same subset of benchmarks used in the first set of experiments. While yices is sometimes faster than CVC3, CVC3 can prove as many or more cases in every category. In total, CVC3 can prove 34 more cases than yices (yices does not support the AUFNIRA division, so we don't count the additional 72 cases CVC3 can prove in this division). Also, CVC3 is significantly faster on the *simplify* and *nasa* benchmarks.

[6] It is worth mentioning that the majority of TPTP benchmarks do *not* contain significant theory reasoning and on these, ATP systems are still much stronger than SMT systems.

| | | Fx7 | | yices | | CVC3 | |
|---|---|---|---|---|---|---|---|
| Category | #cases | #unsat | time | #unsat | time | #unsat | time |
| AUFLIA/Burns | 12 | 12 | 0.4292 | **12** | 0.0108 | 12 | 0.0192 |
| AUFLIA/misc | 14 | 12 | 0.6817 | **14** | 0.0500 | 14 | 0.0479 |
| AUFLIA/piVC | 29 | 15 | 0.5167 | **29** | 0.0300 | 29 | 0.1055 |
| AUFLIA/RicAgla | 14 | 14 | 0.6400 | **14** | 0.0257 | 14 | 0.0407 |
| AUFLIA/simplify | 769 | 760 | 3.2184 | 740 | 1.4244 | **768** | 0.7386 |
| AUFLIRA/nasa | 4619 | 4187 | 0.4524 | 4520 | 0.0824 | **4526** | 0.0138 |
| AUFNIRA/nasa | 142 | 48 | 0.4102 | N/A | N/A | **72** | 0.0118 |
| Total | 5599 | 5048 | 0.8696 | 5329 | 0.2681 | **5435** | 0.1168 |

**Table 3.** Comparison of SMT systems

We were also naturally very curious to know how CVC3 compares to Simplify. Results on the *nasa* benchmarks were given above. The other obvious set of benchmarks to compare on is the *simplify* benchmarks. Not surprisingly, Simplify can solve all of these benchmarks very fast: it can solve all 2251 benchmarks in its suite in 469.05 seconds, faster than both yices and CVC3 which take much longer to solve just the 833 benchmarks that were translated into SMT-LIB format. However, Simplify only achieves these impressive results by relying on special formula annotations that tell it which triggers to use. If these annotations are removed, Simplify can only prove 444 of the original 2251 benchmarks. Since the SMT-LIB benchmarks do not have any such annotations, the ability to prove most of the *simplify* benchmarks *automatically* represents a significant step forward for SMT solvers.

Ideally, we would have run Simplify on all of the SMT-LIB benchmarks. Unfortunately, Simplify does not read the SMT-LIB format and we did not have the chance to translate the other benchmarks into Simplify's language. Such translation is non-trivial as it involves moving from a sorted to an unsorted language (translating the *nasa* cases into Simplify's format was easier because both TPTP and Simplify formats are unsorted).

## 7 Conclusion

In this paper, we presented new formalisms and techniques for quantifier reasoning in the context satisfiability modulo theories. Significantly, our results indicate that these techniques make SMT solvers a better choice than ATP systems on some classes of verification conditions that make use of both theory reasoning and quantifiers. Our techniques are also competitive with other state-of-the art SMT solvers. Indeed, there are several benchmarks from the SMT-LIB library that have been solved for the first time using these techniques.

In future work, we plan to explore extensions of these techniques that allow for more substantial completeness claims. In particular, we plan to explore more sophisticated kinds of theory matching and integration of complete techniques such as quantifier elimination for those theories for which it is applicable.
